Abstract

LENA (Low Energy Neutrino Astronomy) has been proposed as a next generation 50 kt liquid scintillator detector. The large target mass allows a high precision measurement of the solar ^8B neutrino spectrum, with an unprecedented energy threshold of 2 MeV. Hence, it can probe the MSW-LMA prediction for the electron neutrino survival probability in the transition region between vacuum and matter-dominated neutrino oscillations. Based on Monte Carlo simulations of the solar neutrino and the corresponding background spectra, it was found that the predicted upturn of the solar ^8B neutrino spectrum can be detected with 5σ significance after 5 y.

Keywords: Solar Neutrinos

PACS 26.65.+t

1. Introduction

The MSW-LMA prediction for the survival probability of solar electron neutrinos $P_{ee}(E_\nu)$ has been confirmed in the energy region of vacuum ($E_\nu \lesssim 1$ MeV) [1] and matter dominated oscillations ($E_\nu \gtrsim 5$ MeV) [2, 3, 4]. Nevertheless, the predicted upturn of the ^8B neutrino spectrum in the transition region between vacuum and matter dominated oscillations could not be detected, as Water-Čerenkov detectors (WCDs) have a too high energy threshold and current liquid scintillator detectors (LSDs) are too small. A test of the MSW-LMA prediction in the transition region is important as new physics, like non-standard neutrino interactions [5] or light sterile neutrinos ($m_{\nu_1} < m_{\nu_0} < m_{\nu_2}$, where the sterile neutrino ν_s is mainly present in the mass eigenstate ν_0) [6], could influence P_{ee} in this region.

Compared to current solar neutrino detectors, the advantage of the proposed LENA detector [7] is the combination of a ~ 200 keV energy threshold as well as a huge target mass. Thus, the external gamma background, which currently prevents a

measurement of the solar ^8B spectrum below 3 MeV in Borexino [2], can be suppressed by self-shielding. This enables the measurement of the ^8B spectrum with an unprecedented threshold of 2 MeV. Hence, LENA can probe the MSW-LMA prediction over a large part of the transition region.

The present work discusses the sensitivity of LENA to detect the predicted upturn of the ^8B spectrum at low energies. In Sec. 2 the planned detector setup is briefly presented. The simulation of the expected solar neutrino and background spectra is discussed in Sec. 3 and Sec. 4. The analysis of the simulated data is presented in Sec. 5. Finally, the detection potential for the upturn of the solar ^8B spectrum is discussed in Sec. 6.

2. The LENA Detector

The neutrino target consists of ~ 50 kt of liquid scintillator based on linear-alkyl-benzene (LAB), that is enclosed in a cylinder with 14 m radius and 96 m height [8]. The emitted light is detected by photomultiplier tubes (PMTs) that are mounted with non imaging light concentrators (LCs) inside individual pressure encapsulations that are filled with a non-scintillating buffer liquid. The apertures

Email address: randolph.moellenberg@ph.tum.de (R. Möllenberg)

of these optical modules are located at the boundary of the target volume at a radius of 14 m. The corresponding effective optical coverage is $\sim 30\%$. The radius of the cylindrical concrete tank is 16 m, so that the target volume is shielded by 2 m of liquid scintillator. A muon veto formed by gas detectors is placed above the detector tank and provides auxiliary information for the reconstruction of cosmic muon tracks. In order to identify and reconstruct inclined muon tracks, an instrumented water volume surrounding the tank serves as an active Water-Cherenkov muon veto and shields the target volume from fast neutrons.

The preferred location for the detector is the Pyhäsalmi mine in Finland. The detector cavern is shielded by 1400 m of rock coverage, corresponding to ~ 4000 m water equivalent (w.e.). Hence, the cosmic muon flux will be reduced to $\sim 0.2 \text{ m}^{-2} \text{ h}^{-1}$ [9], which is about five times less than in Borexino.

3. Simulation of the Solar Neutrino Spectra

There are two possible detection channels for solar ^8B neutrinos in LENA. The elastic neutrino electron scattering (ES) channel and charged current reactions of ν_e 's on ^{13}C (^{13}C channel).

3.1. Elastic Neutrino Electron Scattering

In the ES channel, a neutrino scatters elastically off an electron, which is subsequently detected. As the energy of the recoil electron depends on the scattering angle, the measured recoil spectrum is a convolution of the solar neutrino spectrum and the electron recoil spectrum at a given neutrino energy.

The simulation of the electron recoil spectra was split into two parts. First of all, the differential events rates for neutrinos from different fusion reactions were calculated according to the BS05(AGS, OP) standard solar model [10]. Using these differential events rates, 10^6 electron events were simulated with a GEANT4 [11] based Monte Carlo (MC) simulation of the LENA detector [12]. The events were homogeneously distributed over the target volume, so that possible position dependent effects are considered. Afterwards, the visible energy was reconstructed from the event position and the number of detected photons [12].

Figure 1 shows the resulting electron recoil spectra. At low energies, the ^7Be and the pep neutrinos have the largest event rate, preventing a detection of ^8B neutrinos below $\sim 1.4 \text{ MeV}$. Above

Figure 1: The simulated visible energy spectra for solar neutrinos with $P_{ee}(E_\nu)$ according to the MSW-LMA prediction for the ES channel. The spectral shapes of the neutrino fluxes were taken from [13, 14, 15, 16].

$\sim 1.4 \text{ MeV}$, the ^8B spectrum is dominant and surpasses the hep spectrum by more than two orders of magnitude.

3.2. Charged Current Reaction on ^{13}C

The charged current reaction of electron neutrinos on ^{13}C ($\nu_e + ^{13}\text{C} \rightarrow ^{13}\text{N} + e^-$) has a threshold of 2.2 MeV . Thus, it is another possible detection channel for solar ^8B neutrinos. Due to the kinematics of the reaction, the recoiling ^{13}N nucleus has only a few keV kinetic energy. Hence, the neutrino energy can be reconstructed on an event-by-event basis by measuring the electron energy. The subsequent β^+ decay of the ^{13}N nucleus ($\tau = 862 \text{ s}$) causes a delayed coincidence signal, which can be used to distinguish signal from background events. Hence, ^{13}C events will be selected by the spatial and timing coincidence between prompt and delayed signals. Although the cross section is about 10 times larger than the cross section of the ES channel [17], the event rate is almost two orders of magnitude lower due to the low isotopic abundance of ^{13}C (1.07%). Nevertheless, the measurement of the unconvoluted shape of the solar ^8B neutrino spectrum with the ^{13}C channel allows an energy dependent measurement of P_{ee} , as the unoscillated solar ^8B flux is known from the NC measurements of the SNO experiment [18].

4. Simulation of the Background Spectra

There are three different types of background present in the ES channel: external gamma rays

	^{40}K	^{238}U chain	^{232}Th chain
Tank	13 MBq	1.1 GBq	178 MBq
PMTs	14 kBq	229 kBq	24 kBq
LCs	0.86 kBq	13 kBq	41 kBq

Table 1: The gamma rates above 250 keV of the different detector components.

that are emitted by the tank, the PMTs and the LCs, cosmogenic radioisotopes produced in-situ by traversing muons and intrinsic radioactive background. A background for the ^{13}C channel is caused by the accidental coincidences of these backgrounds and of ES interactions of solar neutrinos.

Based on the assumed radiopurity of the tank [8], PMTs and LCs [19] (see Table 1), the external gamma ray background was simulated with the GEANT4-based LENA Monte Carlo simulation [12]. It was found that no external gamma background is present above 3.5 MeV. For lower energies, the rate can be reduced to a negligible level by applying a fiducial volume cut. The corresponding fiducial volume is 48 kt above and 19 kt below 3.5 MeV.

Cosmogenic radioisotopes are produced inside the target volume by spallation reactions of cosmic muons on carbon nuclei. The majority of the produced radioisotopes have a lifetime of less than ~ 1 s [2, 20]. Hence, the decays can easily be identified by the time coincidence to the parent muon, without introducing a large dead time. The remaining cosmogenic isotopes with a longer lifetime are ^{11}C (β^+), ^{10}C (β^+) and ^{11}Be (β^-) (see Table 2). The spectral shapes of these isotopes were obtained from the GEANT4-based LENA Monte Carlo simulation. Afterwards, the measured rates of the Borexino experiment [2, 1] have been scaled to the Pyhäsalmi location, using the muon flux of the two sites¹. Below 2 MeV, the ^{11}C background is about two orders of magnitude larger than the solar ^8B neutrino signal. Hence, the end of the ^{11}C spectrum defines the energy threshold for the detection of solar ^8B neutrinos. As ^{10}C and ^{11}Be have a much shorter lifetime than ^{11}C , it is possible to reduce the background from these isotopes by vetoing a cylinder with 2 m radius around each traversing muon for $\Delta t = 4 \cdot \tau(^{10}\text{C}) = 111.2$ s. As the muon rate in the fiducial volume is $\sim 135 \text{ h}^{-1}$,

¹Note that no scaling for the slightly different mean muon energy was applied.

Isotope	Q-Value	Life time	Rate [cpd/kt]
^{11}C	2.0 MeV	29.4 min	54
^{10}C	3.7 MeV	27.8 s	1.0
^{11}Be	11.5 MeV	19.9 s	$6.4 \cdot 10^{-2}$

Table 2: List of the cosmogenic radioisotopes with life times above 2 s.

the introduced dead time amounts to about 10 % of the total exposure, which is still acceptable.

Figure 2: The simulated visible energy spectra of the cosmogenic and intrinsic radioactive background. A spacial and time cut around each muon was applied to reduce the cosmogenic background and the external gamma background was suppressed to a negligible level by a fiducial volume cut.

Besides cosmogenic isotopes, there is also a background from intrinsic radioimpurities in the scintillator. As the amount of radioimpurities in the LENA detector is not known at the moment, it was assumed in the following that the radiopurity levels of the Borexino experiment² ($c(^{232}\text{Th}) = (6.5 \pm 1.5) \cdot 10^{-18} \text{ g/g}$) [2] are reached. The only intrinsic beta-emitting³ radioisotopes in the Borexino detector with a Q-Value above 2 MeV are ^{214}Bi (^{238}U chain, $Q=3.3$ MeV) and ^{208}Tl (^{232}Th chain, $Q=5.0$ MeV) [2]. ^{214}Bi can be tagged by the subsequent decay of ^{214}Po and is thus neglected in the following [2]. ^{208}Tl is produced by the alpha decay of ^{212}Bi which also decays into ^{212}Po ($\tau = 0.4 \mu\text{s}$) with 64 % branching ratio. Hence, the

²Note that the radiopurity levels of the first data taking phase of Borexino are used and that the current radioactive background rates in Borexino have been substantially improved by several purification campaigns.

³Alpha emitters above 2 MeV do not pose a background as their light emission is quenched in a liquid scintillator.

amount of ^{208}Tl can be determined from the observed number of ^{212}Bi - ^{212}Po coincidences. Figure 2 shows the resulting cosmogenic and intrinsic radioactive background spectra.

The accidental background for the ^{13}C channel has been calculated (see Figure 3) based on these spectra. Due to the relatively long life time of the ^{13}N nucleus, a large amount of background is present below 5 MeV reconstructed neutrino energy. Above 5 MeV, the accidental background is at least one order of magnitude below the solar ^8B signal. Thus, the energy threshold for the ^{13}C channel is set to 5 MeV neutrino energy.

Figure 3: The accidental background spectrum for the ^{13}C channel, using a fiducial volume with 11 m radius. Furthermore, the expected ^8B spectrum is shown for comparison.

5. Analysis Procedure

In order to determine the sensitivity for the detection of the upturn of the solar ^8B neutrino spectrum, the potential to distinguish the MSW-LMA prediction from a simple test model with $P_{ee}(E_\nu) = \text{const}$ was investigated. Using the previously simulated neutrino and background spectra, 10^5 five year long measurements of the ^8B neutrino spectrum were simulated with the ROOT package [21]. Afterwards, the MC data sets were analyzed independently for the ^{13}C channel and the ES channel. The accidental background was subtracted from the ^{13}C channel to retrieve the oscillated solar ^8B spectrum. Afterwards, this spectrum was divided by the unoscillated solar ^8B spectrum to determine $P_{ee}(E_\nu)$. Note that the accidental background spectrum can be precisely determined from the measured total spectrum of the ES channel. Finally, $P_{ee}(E_\nu)$ was fitted with the MSW-LMA pre-

diction and with the $P_{ee}(E_\nu) = \text{const}$ model, using a χ^2 minimization. The normalization was treated as a free nuisance parameter in both cases. Hence, this analysis is only sensitive to the shape of $P_{ee}(E_\nu)$ and is thus unaffected by the uncertainty of the solar ^8B flux. Figure 4 shows the result for one example measurement. While the MSW-LMA prediction is preferred one, the statistical significance is not enough to exclude the $P_{ee}(E_\nu) = \text{const}$ model. Overall, the average exclusion significance in the ^{13}C channel is below 1σ .

Figure 4: The measured electron neutrino survival probability after 5 years, using the ^{13}C channel. Furthermore, a fit with the MSW-LMA prediction (depicted in green) and with $P_{ee} = \text{const}$ (depicted in red) is shown.

For the ES channel, it is not possible to directly calculate P_{ee} from the measured ^8B spectrum, as the neutrino energy can not be reconstructed on an event-by-event basis. Thus, the simulated spectrum was fitted with the expected spectrum according to the MSW-LMA prediction and the $P_{ee}(E_\nu) = \text{const}$ hypothesis, using a χ^2 minimization with free parameters for the solar neutrino and the corresponding background rates. In order to maximize the statistics, the full 48 kt fiducial volume was used above 3.5 MeV, as no external gamma background is present at these energies, while the 19 kt fiducial volume was used below 3.5 MeV. As the contributions of the cosmogenic and intrinsic radioactive background can be measured independently, pull-terms were added to the χ^2 function to maximize the sensitivity [22]:

$$\chi_{\text{tot}}^2 = \chi^2 + \chi_{\text{pull}}^2, \quad \chi_{\text{pull}}^2 = \sum_{j=1}^k \frac{(\lambda_j - \mu_j)^2}{\sigma_{\lambda_j}^2}, \quad (1)$$

where k is the number of parameters with prior

information, λ_j is the fit value of the parameter j and μ_j is the expected value of the parameter j , with σ_{λ_j} uncertainty. The uncertainty for the cosmogenic backgrounds were taken from the KamLAND (^{10}C and ^{11}Be) [20] and the Borexino experiment (^{11}C) [1], while the uncertainty for the ^{208}Tl rate was estimated from the expected number of ^{212}Bi - ^{212}Po coincidences. Figure 5 shows the results of the fit for one example measurement. Above $\sim 3\text{ MeV}$ visible energy, the data is consistent with both the MSW-LMA prediction and with the $P_{ee} = \text{const}$ hypothesis. But below $\sim 3\text{ MeV}$, the MSW-LMA prediction is clearly favored, which shows the importance of measuring the ^8B spectrum below 3 MeV , which is not possible with current WC and LS detectors.

Figure 5: The total spectrum for the ES channel after 5y measuring time. Furthermore, a fit according to the MSW-LMA prediction (depicted in green) and according to $P_{ee} = \text{const}$ (depicted in red) is shown.

In the last step, the results from the ^{13}C and the ES channel were combined by adding the χ^2 values of the corresponding fits. Using these values and the number of degrees of freedom, the probability that the MC data sample is consistent with the MSW-LMA prediction or the $P_{ee}(E_\nu) = \text{const}$ model was calculated. In order to suppress statistical fluctuations, this process was repeated for each data sample. Finally, the probability that the $P_{ee}(E_\nu) = \text{const}$ model can be excluded with 5σ significance, which is equivalent to a detection of the upturn of the ^8B spectrum, was calculated, assuming that the MSW-LMA prediction is correct.

measuring time	prob. for a 5σ det.
2 years	43.4 %
3 years	92.5 %
4 years	99.8 %
5 years	$> 99.9\%$

Table 3: The probability to detect the upturn of the solar ^8B spectrum, for measuring times ranging from 2y to 5y.

6. Results

Table 3 shows the probability for a 5σ detection of the upturn of the solar ^8B neutrino spectrum, as a function of the measurement time. After 2 years, the upturn can be detected at 5σ significance for over 40% of all MC data sets, assuming that the MSW-LMA prediction is correct. After 5y, the upturn was detected for each data set. Hence, in case that the upturn is not detected after 5y, the MSW-LMA prediction would be ruled out and new physics must be present that reduce $P_{ee}(E_\nu)$ in the transition region. Comparing the two detection channels, it was found that the sensitivity of the ES channel is much larger than the ^{13}C channel, due to the larger statistics. Nevertheless, the ^{13}C channel still provides an important cross check of the results.

While the amount of cosmogenic background can be precisely estimated for the assumed rock coverage, it is much harder to estimate the intrinsic radioactive background. Hence, the analysis was repeated for a 100 times larger intrinsic radioactive background than in Borexino. Table 4 shows the detection potential for the upturn of the solar ^8B neutrino spectrum in this pessimistic scenario. While the detection potential is of course decreased, the effect of the increased background is not very strong and the upturn can still be detected at 5σ significance after 5y. The reason for this behaviour is that the important energy region below 3 MeV is not affected by the larger ^{208}Tl background. Hence, a precision test of the MSW-LMA prediction is possible with LENA even if radiopurity conditions are substantially worse than in Borexino.

7. Conclusions

Present-day experiments lack the capability for a precision measurement of the electron neutrino survival probability P_{ee} in the transition region between vacuum and matter dominated oscillations

measuring time	prob. for a 5σ det.
2 years	34.6 %
3 years	86.7 %
4 years	99.4 %
5 years	> 99.9 %

Table 4: The probability to detect the upturn of the solar ^8B spectrum, for measuring times between 2y and 5y and for a 100 times larger intrinsic radioactive background than in Borexino.

($1\text{ MeV} \lesssim E_\nu \lesssim 5\text{ MeV}$). LENA will offer an excellent opportunity to close this gap in the determination of P_{ee} by a high-statistics, low-energy-threshold measurement of the solar ^8B neutrino spectrum. Due to its large target mass, the external gamma background, that currently prevents a measurement below 3 MeV electron recoil energy in Borexino, can be efficiently suppressed by a stringent fiducial volume cut. This allows a measurement of the solar ^8B neutrino spectrum with an unprecedented energy threshold of 2 MeV.

In the present work, the detection potential for the spectral upturn of the solar ^8B spectrum that is predicted by the MSW-LMA solution was analyzed. It was found that the spectral upturn can be detected at 5σ significance after 5y measuring time, even if the intrinsic radiopurity level of the scintillator is two orders of magnitude worse than achieved in Borexino. In case that the upturn of the solar ^8B neutrino spectrum is not found, the measurement would rule out the MSW-LMA prediction and show that new physics decrease P_{ee} in the transition region between vacuum and matter dominated oscillations.
